

Parallelised Data Processing

An investigation into the development of a tool for processing queries across a cluster of nodes.

Introduction

1.1 Background

1.2 Prior Work

Distributed Data Processing has existed conceptually since as early as the 1970s. A key paper by Philip Enslow Jr. from this period [8] sets out characteristics across three 'dimensions' of decentralisation - hardware, control and database. Enslow argued that these dimensions defined a distributed system, while also acknowledging that the technology of the period was not equipped to fulfil the goals he laid out.

Research into solutions for distributed data processing has generally resulted in two kinds of solutions [16]:

- Batch processing: where data is gathered, processed and output all at the same time. This includes solutions like MapReduce [6] and Spark [17]. Batch processing works best for data that can be considered 'complete' at some stage.
- Stream processing: where data is processed and output as it arrives. This includes solutions like Apache Flink [5], Storm [15], and Spark Streaming [3]. Stream processing works best for data that is being constantly generated, and needs to be analysed as it arrives.

MapReduce [6], a framework introduced by Google in the mid 2000s, could be considered the breakthrough framework for performing massively scalable, parallelised data processing. This framework later became one of the core modules for the Apache Hadoop suite of tools. It provided a simple API, where developers could describe a job as a *map* and a *reduce* step, and the framework would handle the specifics of managing the distributed system.

While MapReduce was Google's offering, other large technology companies had similar solutions, including Microsoft, who created DryadLINQ in 2009 [9]. However, due to the massive success of MapReduce, Microsoft discontinued DryadLINQ in 2011.

MapReduce was not without flaws, and many papers were published in the years following its initial release which performed performance benchmarks, and analysed its strengths and weaknesses [11]. Crucially, MapReduce appears to particularly struggle with iterative algorithms, like the PageRank algorithm used by Google's own search engine. A number of popular extensions to MapReduce were introduced to improve the performance on iterative algorithms, like Twister [7] and HaLoop [4] both in 2010.

MapReduce's popularity also resulted in a number of tools being created to improve its usability and accessibility. Hive [14] is one such tool, which features a SQL-like language called HiveQL to allow users to write declarative programs that compiled into MapReduce jobs. Pig Latin [13] is similar, and features a mixed declarative and imperative language style that again compiles down into MapReduce jobs.

Further tools in the wider areas of the field were introduced around 2010, including another project by Google named Pregel [12], specialised for performing distributed data processing on large-scale graphs.

In 2010, the first paper on Spark [19] was released. Spark aims to improve upon MapReduce's weaknesses, by storing data in memory, and providing fault tolerance by tracking the 'lineage' of data. This means for any set of data, Spark knows how the data was constructed from another persistent, fault tolerant data source, and can use that to reconstruct any lost data in the event of failure. This in-memory storage, known as a resilient distributed dataset (RDD) [18] allows Spark to improve on MapReduce's performance for iterative jobs, whilst also allowing it to quickly perform ad-hoc queries. Effectively, Spark is strong at performing long batch jobs, as well as short interactive queries. This is something that I would like my solution to feature, as users of the framework will need to design long-running scripts to run on large amounts of data, as well as run ad-hoc queries to perform investigation.

Spark quickly grew in popularity, with a number of extensions being added to improve its usability, including a SQL-style engine with a query optimiser [2], as well as an engine to modify Spark to support stream processing [3]. A second paper released in 2016 [17] stated that Spark was in use in thousands of organisations, with the largest deployment running an 8,000 node cluster holding 100PB of data. One area where Spark struggles is with grouped data, as performing grouped operations requires shuffling the data between all nodes. I aim to improve upon this in my solution through the design of the system as a whole.

More recent research indicates that the future of the field is moving away from batch processing, and towards stream processing for data that is constantly being generated. A 2015 paper by Google [1] argues that the volumes of data, the fact that datasets can no longer ever be considered 'complete', along with demands for improved insight into the data means that streaming 'dataflow' models are the way forward. Google publicly stated in their 2014 'Google I/O' Keynote [10] that they were phasing out MapReduce in their internal systems. The data I will be using is not being received at this constant rate, and as such designing for a streaming solution is not required in this case.

1.3 Project Aims

Design

After conducting my review of previous work, I spent time producing a high-level design for my solution. In particular, I analysed what features it needed to have, what technologies I would use, and the overall architecture. The aim of this was to ensure that the limited development time I had was always spent producing the most useful features.

2.1 MoSCoW Requirements

Before considering specific technologies and frameworks, I produced a list of MoSCoW requirements. Each requirement in the table below has two extra columns. The first column represents whether the requirement is Functional (F) or Non-Functional (NF), and the second column represents requirements that Must (M), Should (S) or Could (C) be completed.

F / NF	Priority	Requirement Description				
Domain Specific Language - Expressions						
F	M	The language must support 5 data types: integers, floats, booleans, strings				
		and date-time objects.				
F	M	The language must allow users to reference a field in the current dataset.				
F	M	The language must allow users to reference a constant value, which can take				
		one of the data types defined above.				
F	M	The language must support arithmetic operations like add, subtract, multiply,				
		division and modulo.				
F	M	The language must support string slicing and concatenation.				
F	S	The language should utilise polymorphism in add operations to apply string				
		concatenation, or arithmetic addition depending on the data types of the				
		arguments.				
F	С	The language could be designed in such a way to allow the user to define their				
		own functions.				
NF	S	The language should be intuitive to use, with SQL-like syntax.				
Domain Specific Language - Comparisons						
F	M	The user must be able to provide expressions as inputs to comparison opera-				
		tors.				
F	M	The language must support equals, and not equals comparisons				
F	M	The language must support inequalities, using numerical ordering for number				
		types, and lexicographic ordering for strings.				

F	M	The language must support null and not null checks.
F	S	The language should support string comparisons, including case sensitive and insensitive versions of contains, starts with, and ends with.
F	S	The language should allow the user to combine multiple comparison criteria using AND and OR operators.
		Data Processing
F	M	The system must allow the user to write queries in Python.
F	M	The system must allow users to apply Select operations on datasets, applying custom expressions to the input data.
F	M	The system must allow users to apply Filter operations on datasets, applying custom comparisons to the input data.
F	M	The system must allow users to apply Group By operations on datasets, which take a number of expressions as unique keys, and a number of aggregate.
F	M	The Group By operation must allow users to apply Minimum, Maximum, Sum and Count aggregate functions to Group By operations.
F	C	The system could allow users to apply Distinct Count, String Aggregate, and Distinct String Aggregate aggregate functions to Group By operations.
F	S	The system should allow users to join two datasets together according to custom criteria.
NF	S	The complexities of the system should be hidden from the user; from their perspective the operation should be identical whether the user is running the code locally or over a cluster.
	L	Cluster
F	M	The system must allow the user to upload source data to a permanent data store.
F	M	The orchestrator node must split up the full query and delegate partial work to the worker nodes.
F	M	The orchestrator node must collect partial results from the cluster nodes to produce the overall result for the user.
F	M	The orchestrator node must handle worker node failures and other computation errors by reporting them to the user.
F	S	The orchestrator should perform load balancing to ensure work is evenly distributed among all nodes.
F	C	The orchestrator could handle worker node failures by redistributing work to active workers.
F	M	The worker nodes must accept partial work, compute and return results to the orchestrator.
F	M	The worker nodes must pull source data from the permanent data store.
F	M	The worker nodes must report any computation errors to the orchestrator.
F	S	The worker nodes should cache results for reuse in later queries.
F	S	The worker nodes should spill data to disk storage when available memory is low.

2.2 Design Choices

From the MoSCoW requirements I had a number of decisions to make regarding what languages and technologies I would use to implement my solution.

2.2.1 Language

Frontend Python was selected as the language of choice for the frontend. This is because the intended users of my solution are most experienced with Python and SQL, which should make it easier for them to adopt and use my solution.

Orchestrator and Worker Nodes Both the orchestrator and worker nodes would use the same language, which would reduce overhead as the same codebase could be used for both parts of the system. When selecting a language, I firstly had to decide whether I would use a language with automatic or manual garbage collection (GC). Choosing a manual GC language would theoretically allow for increased performance, but I also felt that it would slow my development down significantly, as I would have to spend time handling GC myself. Therefore, I ruled out these languages.

The remaining options were a range of object-oriented and functional languages. I knew that much of the implementation would require iterating over lists of items, and functional languages are strong at this because of their use of operations like map and reduce. However, I did not have any experience using purely functional languages like Haskell for large software engineering projects, and so ruled these out. I also knew that the solution would need to perform large amounts of CPU intensive processing, so a language with strong support for parallelisation was preferable. This ruled out languages like Python and JavaScript which are largely single-threaded; both support some form of parallelisation, but much more manual intervention by the developer is required.

In the end, I chose Scala, which is built on top of Java. It features a mix of both object-oriented, and functional paradigms, with built-in support for parallelisation and threading. This would allow me to leverage my previous experience writing large solutions in object-oriented languages, while making use of the functional programming style when convenient.

2.2.2 Runtime

2.2.3 Persistent Storage
